(54) Title: MODULAR UNINTERRUPTIBLE POWER SUPPLY

(57) Abstract: A modular uninterruptible power supply is disclosed, which provides complete redundancy for all components required for UPS operation. Novel aspects of the invention include design of the modules and their interconnection and interoperability, as well as improved operation techniques applicable to UPS systems generally.

MODULAR UNINTERRUPTIBLE POWER SUPPLY

CROSS REFERENCE TO RELATED APPLICATION

5 This application claims the benefit of U.S. Provisional Application serial number 60/183,522, filed February 18, 2000, having the same title and naming the same inventors as this application.

BACKGROUND OF THE INVENTION

10 The present invention relates to the field of uninterruptible power supplies. More particularly, the invention is a modular UPS which provides numerous advantages over prior art UPS systems. Among the advantages provided are scalability, redundancy, and ease of maintenance by the end user.

BRIEF SUMMARY OF THE INVENTION

15 The modular UPS of the present invention includes numerous novel features not found in prior art devices. The modular design is facilitated by modules that make up the UPS that can be installed in various locations in the frame. Flexible location in the frame is enabled by a novel connector, which also provides the capability for the user to service the equipment by replacing modules without being exposed to hazardous conditions. Use of multiple modules is facilitated by a novel current sharing system between various
20 power modules. Novel battery module intelligence is provided that enables or enhances various battery performance aspects as well as extends battery life and decreases the risk of cascading battery damage. Improved battery capacity and run time determination methods are also provided that result in more accurate determination of run time available, enabling the operator to shut down critical equipment before load power is terminated by the exhaustion of battery power. Also provided is a novel technique for switching the UPS to bypass power in the event of a failure, which provides increased reliability by eliminating semiconductor components that are a frequent source of failure in prior art UPS systems. Another aspect of the invention is a novel shipping pallet that provides both additional structural rigidity and a simplified means for unloading and
25 reloading the unit.

DETAILED DESCRIPTION OF THE INVENTION

The uninterruptible power supply (UPS) of the present invention is illustrated in Fig. 1. All of the UPS components are housed in frame. UPS components include the primary controller, the standby controller, the power modules, the battery modules, and the user interface. The UPS employs a modular design and is intended for use with workstations, servers, network, telecommunications or other sensitive electronic equipment. It provides continuous high quality AC power to such equipment protecting the equipment from power failure and interference from blackouts, brownouts, surges, and noise. The modular design provides expandability and redundancy. Frame can accommodate multiple power modules. The addition of power modules increases the load capacity of the UPS. Frame can also accommodate multiple battery modules. Addition of battery modules extends the run time of the UPS.

In addition to providing expandability, the modular construction of the UPS also provides a high level of system redundancy, which is illustrated in Fig. 3. AC power is received at input and passes through input EMI filter to an interconnect, which is part of the UPS frame. From this interconnect, power passes through a plurality of power modules, through output EMI filter and output transformer to a load. If any of the power modules fail the remaining power modules supply power. If all power modules fail power is supplied through bypass. If the utility power at input fails, battery modules provide DC power through interconnect to power modules. Multiple battery modules provide excess capacity and also provide redundancy should one or more battery modules fail. Primary controller controls the UPS system with standby controller operating in lockstep and ready to assume control if the primary controller fails.

Frame comprises a plurality of bays to hold power modules and battery modules. In one embodiment, power modules may be accommodated in any of the upper four bays, and battery modules may be accommodated in any bay. Restricting power modules to the upper four bays prevents overloading the UPS capacity by installing too many power modules. User interface module is located above the power and battery module bays. Behind the removable user interface are the control interface slots, which contain the primary controller and the standby controller. The back of frame contains output transformer and the communications interface. User interface module is the main

- 4 -

communication link between the UPS and the user. From the user interface, the user can check the status of the UPS, custom configure the UPS, and review log events.

Power module provides conditioned power for the UPS output. In one embodiment, each power module is an independent 4 kVA unit, which may be housed in 5 one of the top half of the bays of the frame. An embodiment having twelve bays may accommodate up to six power modules.

Battery modules provide back-up power in the event of an AC failure. In one embodiment of the invention, the battery module comprises ten individual 12-volt batteries and various control circuitry encased in a plastic box.

10 The primary controller and the standby controller are the communications backbone of the UPS. These controllers connect to user interface to provide the user with information about the condition of power modules, battery modules, and other UPS systems. The primary controller and standby controller also process power and battery module information and configure and regulate the UPS accordingly. The standby controller 3 is provided to prevent a total UPS failure if the primary controller fails.

15 A block diagram of the UPS is shown in Fig. 2. Alternating current (AC) power is supplied at input. AC power flows from input to the input EMI (electromagnetic interference) board, which provides power conditioning and filtering to prevent the UPS from interfering with other electrical or electronic systems and to protect the UPS and connected load from EMI generated by other equipment. From the input EMI board power may flow along a first power path to output and bypass contractor or along another a second power path to power module. During normal operation, the first power path is used, and power modules supply AC power for the critical load. The power modules receive AC power from the utility input and convert it to DC power, which is used to charge the batteries and to power the power modules' inverters, which produce stable, regulated AC power for the critical load at output. If a UPS component failure renders the UPS inoperable or if it is otherwise desirable to take the UPS out of the power path, output and bypass contactor closes, creating a direct power path from input directly to optional output transformer and output. Power may also bypass the UPS 20 through manual bypass, which may be manually closed by the operator.

25 Power module and battery module are connected to control interface, which in turn connects to primary controller and standby controller. Primary controller controls

- 5 -

the UPS, including power module and battery module, unless the standby controller detects a failure of primary controller. If the standby controller detects a fault in primary controller, standby controller assumes control of the UPS.

Control interface also connects to user interface. User interface allows the operator to change and set operating parameters for the UPS. User interface 6 also provides the means whereby messages are passed from the UPS control system to the operator.

The UPS of the present invention has five modes of operation: (1) normal mode, (2) back up mode, (3) auto restart mode, (4) recharge mode, and (5) bypass mode. During normal UPS operation, power flows from input EMI filter to power module. Power module first converts the incoming AC power to DC power, a portion of which is used to charge the batteries in battery module. Power module converts the remainder of the DC power back into AC power at a highly regulated voltage and frequency. The AC power is supplied to output EMI board, which provides power conditioning and prevents EMI from adversely affecting the connected load. From output EMI board power flows to output and bypass contactor, which during normal operation directs power flow through an optional output transformer to output. Output transformer isolates the critical load connected at output from the input AC power source and the UPS. The optional output transformer also transforms the voltage supplied by power module to match the voltage of the critical load connected at output.

If utility power fails, the UPS enters back up mode and power modules generate convert DC power supplied by the battery modules into AC power for the critical load. The voltage to critical load at output will not be interrupted during the failure or restoration of the utility AC source. When the UPS is operating in backup mode, an audible alarm sounds to so notify the user. Once the unit enters back-up mode it will continue in backup mode until the utility returns or until the batteries are exhausted. Once the battery is exhausted, the unit goes to sleep. If the utility returns while the UPS is operating in the back-up mode, the unit will return to the normal mode of operation and charge the batteries. Once the utility returns the unit re-qualifies itself and determines the auto restart setting. If auto restart is enabled, the unit will automatically restart, enable the output, and, once the auto restart parameters have been met, the

- 6 -

batteries will begin to be charged. If auto restart is not enabled then the unit waits for the user to turn the output on, during this waiting period the batteries are charging.

When utility AC power is restored after an outage, the UPS enters auto restart mode, in which the UPS automatically re-starts and begins supplying power to the critical load. After the UPS enters auto restart mode and resumes supplying power to the critical load, the unit recharges the battery modules until fully charged.

The UPS has two bypass modes, each of which provides an alternate power path to the critical load bypassing power modules. The UPS will enter automatic bypass mode in the event of an internal failure or an overload of the UPS. In the automatic bypass mode, the UPS will automatically transfer the critical load to the bypass source, which may be either the normal AC utility source connected at input or a completely separate source connected at a bypass input (not shown). If the UPS must be taken out of service for maintenance or repair, the UPS may be placed in manual bypass mode. Manual activation of the bypass will cause an immediate transfer of the load to the bypass source. All power module and battery charging operations are inhibited until the manual bypass switch is moved back to the UPS position, at which time the UPS enters the auto restart mode.

System Interconnect Module

Referring again to Fig. 3, the UPS frame also serves as the system interconnect module. The system interconnect module provides the connection between the control module (primary or standby) and the user interface module. The system interconnect module also provides all interconnections between the power modules, battery modules, utility input, and output to the critical load. The automatic and manual bypass components are also included in the system interconnect module, as are current sensing, power sharing, and fault tolerance circuitry. Finally, the system interconnect module also includes the communication interface and the interface for battery monitoring of both internal battery modules and external battery cabinets.

Control Modules

The control module can be either the primary controller or the standby controller. Control module redundancy provides a means whereby the primary controller can remove itself from control of the UPS and allow the standby controller to take control upon failure of primary controller. The primary controller's control signals are

- 7 -

transmitted through fault tolerant tri-state drivers. The primary controller and the standby controller both monitor the status of the other controller. Firmware in the controllers determines the status of the critical bus, and all output signals are digital.

Power Modules

A high-level block diagram of the power module is illustrated in Fig. 5. The power module comprises an input three-phase rectifier, and power factor correction circuit, control power supply (not shown), battery charger (not shown), half-bridge inverter, and analog and digital control circuits (not shown). The half bridge PWM inverter produces a single-phase sine wave output. The power module could also be constructed using a three phase inverter. The inverter output passes through an LC filter, made up of output inductor and output capacitor, before reaching load. Inverter comprises inverter switches, which are insulated gate bipolar transistors ("IGBTs"), and series protection IGBTs. The protection IGBTs are always on during normal inverter operation. The protection IGBTs are turned off when a failure of the power module is detected, disconnecting the inverter IGBTs from the DC bus and preventing back-feeding the failed inverter to the other paralleled inverters in the system. Each IGBT is fitted with a freewheeling diode to allow current to flow during ON/OFF transitions (dead-time).

The inverter output of each power module is coupled in parallel with the inverter outputs of the other power modules. The paralleled inverter outputs share load current and allow redundancy in the case of a power module failure. A power module output relay is used to connect the inverter to the paralleled output bus. When relay is open, the inverter can self-test before connecting to the paralleled inverter output bus. When relay is closed, a built in test continues to monitor the status of the power module. An inverter output fuse on the top board will open if the inverter control circuits are unable to prevent a catastrophic overload. When power module is installed into the UPS frame, two card edge connectors connect signals and power from the power module to the system. Connection is made using the novel safe connector discussed at length below.

The power module control system is schematically depicted in Fig. 4. The primary control element is controller, which may be, for example, a Siemens C505 micro-controller. Controller senses various parameters of the power module and communicates externally through its built-in controller area network ("CAN") controller.

- 8 -

Controller also controls green and yellow LEDs, which display through the front of the power module and communicate status information to the user.

Various analog circuits are used to sense mains and battery voltages, condition the input voltage and current, measure the DC bus voltage, sense DC bus over-voltage conditions, and adjust the DC bus voltage to the appropriate level. Analog circuits are also used for inverter control purposes. The power module output sine wave is produced by applying pulses of varying widths to the gates of power switches. This technique is known as pulse width modulation (PWM). The PWM signal is produced by comparator, which compares a 20 kHz triangular wave, derived from a digitally transmitted signal, to a reference sine wave, also derived from a digitally transmitted signal. The referenced digital signals are converted into the corresponding analog signals by reference sine wave generator and triangle wave generator. The triangular wave becomes the carrier for the PWM signal used to switch the power devices. Its frequency and magnitude are 20 kHz and \pm 4.2 volts, respectively. Filtering out the fundamental frequency of the PWM pattern transmitted by the system control generates the reference sine wave. For calibration purposes, the sine wave reference can be phase and magnitude adjusted according to the required output voltage and frequency. The sine wave generator features digital potentiometer to adjust the phase of the reference sine wave and a potentiometer to adjust the magnitude of the reference sine wave.

The output of the inverter is current limited using a two step current limit circuit, which allows the inverter to handle linear and crest factor type loads.

A current sharing circuit is used to make sure that when multiple power modules are connected in parallel, each module will equally contribute current to the load. A photo-FET device is used as a variable resistor to electronically adjust the magnitude of the sine wave reference for current sharing purposes.

The second stage of the control circuit is a non-inverting amplifier whose magnitude gain is automatically adjusted according to the current sharing requirement. The adjustment is done by varying the current into the diode of a photo-FET device. The photo-FET operates in a linear region (pinch-off region) and behaves like a potentiometer depending on the current flowing into the diode. The current sharing method employed is discussed in greater detail below.

- 9 -

Inverter output current is sensed differentially to provide improved noise immunity. The current signal comes from a Hall-effect current sensor. A bridge rectifier rectifies the current signal from the sensor. The rectified current signal is converted to a voltage signal, which is sensed by differential amplifier. Amplification of the signal is necessary because this signal is used for current sharing control and the higher signal value improves current sharing accuracy. For input into the micro-controller, the current signal is attenuated to a level compatible with the micro-controller.

AC Current Sharing

To successfully operate multiple power modules in parallel it is necessary to provide a means whereby the power modules can share the load current evenly. Prior art current sharing techniques measured the total output current of the paralleled power modules and divided that current by the total number of power modules to derive a current command value for each power module. There are several problems encountered when using this method. First, it does not account for a failed power module, which can result in one or more power modules being overloaded if one of its counterparts fails. Second, the requirement that the combined output current be measured and divided among the power modules introduces a single point failure mode into the system. If the output current sensing circuitry fails, the entire UPS will become inoperable. It is thus desirable to have a current sharing method that avoids these disadvantages of the prior art.

One method whereby this can be accomplished is described below with reference to Fig. 4. In general, the power module with highest output current places its current value on a current share bus ("IBUS"). The other power modules then adjust their reference current gain to cause the power module to generate a current that matches this value. The AC current sharing system using a common current bus or IBUS has the advantages of: (1) accurate current sharing, (2) good waveform fidelity, and (3) automatic compensation for failed modules. A similar technique for operating DC power modules in parallel is disclosed in U.S. Patent No. 5,157,269 (the '269 Patent) to Mark Jordan and Robert Mammano, which is assigned to Unitrode Corporation. The technique disclosed in the '269 Patent is directed only to direct current (DC) systems, but has been extended by the inventors herein to apply to AC systems.

- 10 -

Each power module measures its output current at the module output inductor using Hall effect current sensor. The current sensor could also be a current transformer or other current sensing device, which are well known to those of ordinary skill in the art. The current sense signal is then rectified by full wave rectifier. The full wave rectified signal is then passed to comparator at input. Comparator compares the module current to the IBUS current received at input. If the module's output current is higher than the IBUS current, diode will be forward biased and the module's current will be put on the IBUS. If the module current is less than the IBUS current, diode will be back-biased, and a signal representing the IBUS current will be present at the cathode of diode. Summing amplifier receives the power module's current at a first input and receives the IBUS current at a second input. Summing amplifier therefore subtracts the module output current from the IBUS current to generate an error signal. This signal drives an adjustable gain amplifier, which may be realized using, for example, a photo-FET device. The greater the error signal, the greater the increase in the gain of current reference amplifier. The gain increase increases the power module's voltage sinewave reference, which will force the power module output current to increase to match the dominant current reflected on the IBUS.

To stabilize the output currents of the paralleled modules, the current differences must be higher than a fixed offset current before current adjustment is made.

An alternative to the IBUS technique described above is the power measurement technique illustrated in Fig. 13. The control circuit is similar to the IBUS control circuit illustrated in Fig. 4, and the basic principles of operation are the same. Using the power measurement technique, the total UPS output power is measured by the main controller, by multiplying the output voltage and current. The controller, which is in communication with the other modules via the CAN interface, then determines the appropriate output per module and sends instructions to modules, which adjust their individual outputs accordingly. Generation of the PWM signal is basically similar to the IBUS technique described above. The advantages of the power measurement technique include: (1) better noise immunity, (2) fewer circuit components, and (3) automatic compensation for failed power modules. Disadvantages of this system (as compared to common current bus system) include: (1) less accurate current sharing, (2) decreased waveform fidelity, and (3) less accurate sharing for step response.

- 11 -

Battery Modules

Batteries are one of the highest failure components in a UPS. One failed battery can cause degradation and failure in other batteries in the system, known as a cascading failure. Therefore, what is needed in the art is a system whereby a failed battery may be isolated from the other batteries in the system. The intelligent battery module of the present invention provides a means whereby the battery module monitors itself and, if it is failing, it can remove itself from the UPS before it adversely affects the other battery modules or the UPS.

Battery module construction is illustrated in Fig. 14, and battery module power wiring is illustrated in Fig. 11. Battery module is a plastic case containing ten 12-volt batteries, comprising a 120-volt battery string, and various electronics mounted on printed circuit board ("PCB"). The required electronics comprise a micro-controller with a controller area network ("CAN") interface to communicate with the other modules, analog battery monitoring circuits, battery fuse, battery relay, front panel LED indicators, and PCB edge fingers carrying power and signals. When battery modules are installed into a UPS frame, the 120-volt battery string in each module is connected in parallel with other battery modules on the UPS battery bus.

The case is a two part plastic box constructed of a lower half and an upper half. The box holds the batteries, control PCB, and front panel PCB. The rear of the box has a slot shaped opening through which a connector can plug onto the control PCB card edge fingers. The front of the box has a label through which a yellow and green LED on the front panel shine. The yellow LED indicates that the battery module needs service, and the green LED indicates normal operation. A relay in series with the battery opens when battery module is removed from the UPS frame, and therefore battery voltage is not present on the card edge fingers when the battery module is removed from the UPS frame.

Quick connects are used to connect the battery wires (not shown) to the control PCB. The battery string is wired in two strings and, each having a total of five series-connected batteries. Each string is connected to the battery module control board and is connected in series through a fuse. A fuse is connected in series with the battery strings for over current protection. An analog temperature sensor is included to monitor the temperature inside the battery module. The battery module also includes a power supply,

- 12 -

which derives its power either from the battery or from the UPS battery bus depending on the mode of operation.

The battery module controller is a Siemens 8-bit micro-controller (8051 derivative) that includes a 128K flash memory and 32K static RAM. The micro-controller has an 8-channel, 8-bit analog to digital (A/D) converter and an integrated CAN 2.0B controller. The flash memory is bank selected as four banks of 32K under software control. The flash memory may be updated through the CAN bus. Extra logic circuitry is included to switch the control signals during flash programming because the code has to run from RAM.

The battery module controller monitors the battery module status, makes the status information available to other modules within the UPS, controls the relay connecting the battery module to the system, records usage statistics, and controls the indicator LEDs based on the battery module status. The battery module controller uses a combination of analog and discrete signals to determine battery module status and to provide information required by the system controller to determine the control actions. These signals are monitored with varying frequency depending upon the state of operation and the signal to be monitored. While in the normal state or the alarm state, the analog signals are monitored every 100 milliseconds. While in the idle state, the analog signals are monitored once every four hours in a burst of sixteen measurements at 100 millisecond intervals. Each analog signal is filtered to minimize the effects of random noise. The filtering is accomplished by computing the average of the previous sixteen measured values for a given signal.

The measured signals are adjusted for the gain and offset corrections as determined by the calibration data. Measured signals include (1) first battery string voltage, (2) second battery string voltage; (3) battery module temperature, (4) battery charge current, and (5) battery discharge current. There are a number of discrete signals that are also periodically monitored. Measured discrete signals include (1) UPS on battery, (2) UPS power off, (3) module removed.

The battery module firmware attempts to keep its batteries available even if internal alarms are detected. Firmware is used to support the battery module's operation for normal usage within the UPS. Battery module firmware also records the following system level or module level information and/or events in EEPROM (1) module serial

- 13 -

number, (2) module hardware compatibility, (3) calibration parameters for A/D channels, (4) total discharge cycles, (5) total operations on battery, (6) total time on battery (in seconds), (7) total counts of over temperature during charging, (8) total complete discharge cycles, (9) total watt-hours delivered on battery, (10) total failures and 5 warnings, (11) total unexpected processor boot events, (12) battery install date, (13) total battery replacements, (14) last failure code, (15) last warning code, (16) total battery module repairs, and (17) total system operation time (in seconds).

For the purposes of understanding the battery module's firmware behavior, the battery module can be thought of as having five states: (1) power off, (2) initialization, 10 (3) normal, (4) idle, and (5) alarm.

In the power off state, the battery module consumes a minimum amount of power from its internal battery. In the power off state, the battery module disables all battery loads, including the battery voltage sensing circuits.

In the initialization state, the battery module executes a built-in self-test, 15 establishes a CAN ID, and initializes the battery module for use. If successful and no failures or warnings exist, the battery module transitions from the initialization state to the normal state, otherwise it transitions to the alarm state.

In the normal state, battery module relay is closed connecting the battery to the external signal. The battery module monitors its own internal status and external control 20 signals and maintains battery module statistics. The battery module will transition from the normal state to the idle state via a received CAN message, or to alarm state if a failure or warning condition occurs.

In the idle state, battery module operation is largely the same as the normal state, except that relay is open, disconnecting the batteries from the UPS system. An external 25 CAN message can place the battery module in this state, preventing the battery from being continuously float charged. The battery module will transition from the idle state to the normal state if UPS transfers to battery or if an appropriate CAN message is received. The battery module will transition from the idle state to the alarm state if an internal failure or warning is detected. Because the battery module is expected to operate 30 in an idle state for up to thirty days at a time, it is important that the load on the batteries be kept to a minimum. To that end, in the idle state, the controller keeps the battery voltage monitoring circuits inactive most of the time. The voltage monitoring circuit is,

- 14 -

however, activated periodically to update the battery voltage readings. In the idle state, the battery module electronics are powered by the external source, not from the internal batteries. However, the sensing resistor strings will always draw the required sense current from the internal batteries.

5 In the alarm state, behavior of the battery module varies depending on whether the abnormal condition that caused the battery module to enter the alarm state is a warning or a failure. If a warning is detected, the battery module remains in the alarm state as long as an abnormal condition persists. Once the abnormal condition clears the battery module transitions to the normal state. If a failure condition is detected, this
10 condition is latched and the UPS persists in the alarm state, even if the condition appears to resolve itself. In other words, once a failure condition is detected, the battery module will remain in the alarm state. This failure condition is retained in non-volatile memory so that it persists even after the controller is rebooted. A failure may be reset only if the battery module receives a CAN message indicating that the failure is to be cleared.
15 Battery module failure conditions include: (1) open cell, (2) shorted cell, (3) high impedance, (4) fuse open, (5) non-zero charge current for an extended period, (6) battery string imbalance, and (7) capacity during discharge below expected limit.

Figure 11 is a power one-line drawing of the battery module. The battery module comprises a battery strings and fuse, relay and current sensor all connected in series.
20 Battery module monitors its own voltage, current, and energy status to determine its state of charge and health. Battery voltage is monitored across the whole string and half of the string, which provides higher resolution and better detection of battery faults. If the half string voltage deviates from its nominal value by more than a specified amount, the intelligent battery module opens its output relay taking itself off line. The battery module is connected to the UPS battery bus. Battery module also includes its internal control power supply. Power supply may be powered from either battery bus, through diode, or from the battery module itself, through diode. It should also be noted that the battery module fuse is disposed between the two halves of the battery string.
25

The fact that the intelligent battery module monitors its own state of charge and
30 health enables the battery module to provide numerous features that were not available using non-intelligent batteries of the prior art. First, the battery module is able to determine when it is failing and take itself off line before it damages the other batteries

- 15 -

or causes a failure of the entire UPS system. In prior art systems, numerous battery failures could cause cascading failures. For example, a failed battery could develop an internal short circuit, which would cause all of the system's charging current to flow into that battery module, thereby starving the other good batteries. When running on battery power, the starved batteries would have less capacity, thereby reducing the systems' available power and decreasing the available battery run time. The intelligent battery module is also able to determine whether, under the current operating circumstances, it should take itself off line. For example, the battery module will not take itself off line if it is discharging and the UPS is running off battery power.

If the battery module controller detects a failure, it opens relay, thereby isolating itself from the UPS battery bus. If the battery module takes itself offline, the battery module controller still receives control power from battery bus enabling it to remain operational even if the battery module has failed. The battery module controller also stores the battery module status in memory, so that the failed module will not place itself back online if it is removed from the UPS and put back in place later. When the battery module takes itself off line, the battery module controller sends a status signal to the system controller indicating that the failed battery module is no longer available. The communication to the system control occurs in two different modes. The first mode is a discrete status signal, and the second mode is a CAN message.

The battery module provides two discrete status signals to the system control. The first status signal indicates whether the module is present, and the second indicates whether the module is active. The technique for generating these signals is illustrated by Fig. 12. Each battery module includes two constant current sources. Construction and application of constant current sources is well known in the prior art. These constant current sources draw power from a +5V reference source located in the UPS frame. The current flows through a sense resistor causing a voltage drop across the resistor that is proportional to the number of connected modules. The voltage drop is measured at point. The number of modules present in the system determines the number of constant current sources, which determines the total current flow through sense resistor and thus the voltage measured at point. This system allows the system controller to determine the number of battery modules present and active, which the system controller uses to determine run time, available power, etc.

- 16 -

The current source arrangement described in the preceding paragraph only identifies the total number of modules available, and does not provide any information concerning which battery module has failed. That information is provided by a controller area network (CAN) message that is passed from the battery module controller to the system control. The CAN message identifies the failed and the cause of the failure, which enables the system control to pass this information to the user through the user interface.

Battery module intelligence also allows battery module to have a sleep mode, which provides extended battery life. When the battery module controller detects that the battery is fully charged, it opens relay, isolating battery string from UPS battery bus. Disconnecting the batteries when charging is complete prevents the batteries from receiving excess charging current that could damage the batteries. It also prevents the batteries from experiencing any voltage ripples that might appear on the battery bus, which decreases the battery's life time. While the battery string is disconnected, the battery module controller is powered by battery bus so that the battery is not unnecessarily drained. The controller will reconnect the battery module to the battery bus by closing relay if the battery module is needed to power the UPS, or to recharge the batteries based on either the charge status or the length of time the battery module has been in sleep mode. If the relay is open and the UPS switches to battery operation, it is critical that the relay coil be energized within 1 millisecond, causing the relay to close within sixteen milliseconds of UPS switching to battery.

The intelligent battery module also senses its own internal temperature. This temperature is used to determine the charging voltage and current to provide optimal charging without damaging the battery. For UPS systems with multiple battery modules installed, the module with the highest temperature governs the charging voltage, which provides the lowest risk of damage to the battery modules. Sensing battery temperature also allows the controller to detect a thermal run away and take the battery module off line before the UPS is catastrophically damaged. If the temperature is very high (greater than 70°C), relay should be opened unless the UPS is operating from battery. Disconnection of the batteries at this temperature minimizes the risk of battery damage or thermally induced battery failure. The temperature of the battery modules is also incorporated into the battery run time calculations, which are discussed in greater detail

- 17 -

below. Finally, the battery temperature sensing also allows the system control to detect faults based on gross temperature differences among the multiple battery modules installed in the UPS system.

Battery module also tracks the amount of energy currently stored in the batteries.
5 Tracking the stored energy requires the battery to track the battery voltage and charging and discharging current. This information is passed to the system control for use in the battery run time determination technique discussed below.

The intelligent battery module monitors its own discharge current to determine how the battery module is operating. When battery module is discharging, the discharge rate is communicated to system control, which determines whether the discharge rate is consistent with the capacity of the individual battery compared with the capacity of the other batteries in the system. If the discharge current is out of tolerance, system controller assumes a fault, which is communicated to the user by way of the user interface. Battery module also uses the discharge current to determine the energy remaining in the battery during the discharge cycle, which is used in connection with the battery run time calculation method discussed below.
10
15

Battery module also monitors its charging current for similar purposes. The charging current multiplied by the charging voltage and summed over time allows the battery module controller to determine the batteries' charge status, which is used in the run time calculation method discussed below.
20

Two circuits are employed to monitor charge and discharge currents into and out of the battery, respectively. The input to the circuits is the voltage drop across a current sense resistor. The voltage drop across the sense resistor is monitored differentially to minimize noise pick up. Each output of the circuits is connected to the battery module controller via a separate analog-to-digital input. The circuit to monitor battery charge current produces a linear voltage corresponding to the charge current. A separate circuit is used to measure discharge current, which also produces a linear voltage corresponding to the discharge current. Separate circuits are used because of the relatively small magnitude of the charging current as compared to discharge current. The current sensing circuits provide the data that, along with the battery sense voltage, are used to determine and calculate the battery strings capacity and health in real time.
25
30

- 18 -

Battery voltage is scaled down and monitored by a combination of a resistor divider in series with a MOSFET. The MOSFET is necessary to break the resistor divider string when the unit is not operational (e.g., sitting on the shelf). Without the MOSFET, current will flow through the divider string and drain the battery power over a period of time. A non-inverting amplifier is used to attenuate the measured voltage so that the required objective can be achieved. This circuit measures the voltage of the entire battery string. The described circuit is duplicated to measure the voltage of half the battery string, which allows comparison of the difference between the full string voltage and the half string voltage to detect a shorted cell. If a shorted cell is detected, the module will take itself offline by opening its series relay.

As noted above, the battery voltage monitoring circuits are not active when the battery module is in the power off state. Additionally, the battery voltage monitoring circuits are activated only periodically when the battery module is in the idle state. This minimizes the battery load and battery discharging when the battery module is not in use.

Batteries have a self-discharge rate and do lose capacity over time even when they are not being used. The intelligent battery module has the capability to calculate this loss of capacity and automatically update its state of charge. The intelligent battery module receives time and date stamps on an interval basis from the system control module. If the battery module is removed from the system, the time and date are stored in memory by the battery module controller. When the battery module is re-inserted into a system, the battery module controller computes the time it has been out of a system and automatically corrects for its lost charge capacity. This method allows much more accurate level of run time predictions and battery capacity calculations. This technique may also be applied if the UPS is turned off. When the UPS is turned back on the battery module automatically adjusts its capacity to adjust for the time that the UPS was off.

Battery Energy Metering

Battery module intelligence facilities battery run time calculation using variables and parameters not previously available for battery run time calculations in UPS systems.

As an example, prior art UPS systems determined remaining battery run time based on battery discharge curves that did not account for battery aging. However, as noted above, the UPS of the present invention is able to track the age of the batteries. As a

- 19 -

result accuracy of the run time calculations by the present UPS is significantly improved over the UPS systems of the prior art, particularly when using older batteries. The battery run time calculation method employed by the UPS of the present invention is more accurate than prior art methods, particularly for older batteries and for batteries that have been exposed to significant temperature variations (i.e., environments not kept at a relatively constant 25°C). Implementing the claimed method with new batteries requires certain assumptions of battery characteristics, supplied by the battery manufacturer. Additionally, implementation of the specific hardware and software to perform these calculations would be within the abilities of one ordinarily skilled in the art having the benefit of this disclosure, and thus these implementation specific details are not discussed in detail.

The method of calculating the remaining battery run time is described as follows: The intelligent battery module provides its empirical energy rating ("EER"), present energy ("PE"), and deliverable energy ("DE") to the system controller. The battery module's empirical energy rating is the amount of energy that was delivered by the battery module during the last full discharge, which is the amount of energy the battery module has demonstrated that it can provide from a fully charged state to a fully discharged state. The present energy of the battery module is the amount of energy presently stored in the battery. The present energy value is always greater than zero and less than the empirical energy rating. The deliverable energy of the battery module is the amount of energy the battery module can deliver. The deliverable energy is computed as a function of the present energy, temperature, and battery loading. Increased battery loading and/or decreased battery temperature decrease the battery module's deliverable energy.

Using the data provided by the battery module, the system controller computes the state of charge ("SOC") and remaining run time ("T"). The calculations performed by the system controller account for battery aging and whether the battery is charging or discharging. The system controller updates the empirical energy rating for each battery module at the end of the discharge event. The state of charge computed by the system controller is calculated on a percentage basis and is the sum of the present energy divided by the empirical energy rating for all battery modules. The system control computes the

- 20 -

UPS remaining run time as the sum of the deliverable energy value for each battery module, divided by the total load on the system.

When a new battery module is used, battery characteristics are assumed based on manufacturer supplied data. Typical assumptions include the following: The empirical energy rating is equal to the manufacturer's rated capacity for the batteries. The present energy stored in the batteries is 90% of the empirical energy rating. The deliverable energy is the present energy times the appropriate temperature and load derating factors. For battery charging, if the battery module's state of charge is greater than 90%, the state of charge is updated as a function of elapsed time, with the transition from 90% to 100% taking seventy-two hours. These parameters are based on typical manufacturer's specifications, such as a charging efficiency of 90% and a forty-eight hour charging time required to go from 90% to 100% charge. Another assumption made during charging of a new battery is that if the state of charge is less than 90% and the battery is rapid charging, 90% of the product of the input charging power and the charging time is added to the present energy. This assumption is also based on the manufacturer's typical specification of 90% charging efficiency. If the battery has a state of charge of less than 90% and is slow charging, i.e., charging current is less than 25% of maximum charging current, then battery charging is assumed to be at a 25% charging rate and 90% efficient. This means that for a charging current less than 25% of the rated charging current, 90% of 25% charging energy times charge time is added to present energy. These assumptions are based on typical values supplied by battery manufacturers and may be adjusted as required to account for battery differences among manufacturers or empirical observation of the batteries' performance.

The battery charging method also compensates for the temperature of the battery module by derating the percentage of energy stored in a battery module as a function of temperature. The percentage of energy stored in a battery that the battery can supply at a given temperature is indicated in the manufacturer's specifications for that battery, and may be represented in the form of a derating curve as illustrated in Fig. 15. The temperature derating factor may also be obtained through battery discharge testing. By inspection of Fig. 15, it may be seen that the derating factor is 100% at a battery temperature of 40°C, meaning that at this temperature the battery can supply 100% of its present energy. This derating factor decreases approximately linearly to a derating factor

- 21 -

of 98% at a battery temperature of -10°C. These specifications are incorporated into the program that determines the run time allowing the run time to more accurately reflect the actual conditions under which the battery is discharging.

The battery run time calculation technique also accounts for the rate at which the battery discharges. This compensation is based on empirical data rather than battery manufacturer specifications. For a given amount of energy taken out of the battery, the battery run time is shortened more the faster the energy is discharged (i.e., a higher power load). The weight given to this factor is determined by empirical testing. The load-based derating factor curve is illustrated in Fig. 16. At a load of 0%, the battery module can deliver 100% of its present energy. This factor decreases to approximately 75% at 100% load and to just over 60% at 170% load.

Run time calculations are made while the battery is discharging. There are two alternative methods of run time calculations, which are combined to generate an accurate run time estimate. The first method decreases the battery module's present energy by the energy actually delivered by the battery, de-rated for load on the battery and battery temperature. This first method is more accurate at the beginning of the discharge cycle, but it does not account for battery changes due to aging, battery failure, or bad charging efficiency assumptions.

The second run time calculation method uses a lookup table that plots deliverable energy vs. battery voltage, with multiple tables stored as a function of percentage load. See Fig. 17. As can be seen by comparing the curves, the 50% load curve, a greater portion of the battery module's energy may be delivered as compared to the 100% load curve. Multiple load curves for various load levels are stored in the controllers memory, which compensates for the load derating factor discussed above. The accuracy of this method increases as the empirical energy rating is updated at the end of a discharge cycle. Because the second method is based on battery voltage, a warning is always provided as the battery approaches the end of discharge. However, the second method is not as accurate near the beginning of the discharge cycle because small battery voltage changes at the beginning of the discharge cycle result in large changes in estimated run time that are unwarranted given the actual amount of energy taken out of the battery. In the second method, the empirical energy rating for each battery module is updated at the end of a discharge event, provided that the battery started at a 100% state of charge. The

- 22 -

empirical energy rating is updated at the end of the discharge cycle to the sum of the delivered energy (adjusted for temperature and load) and the present energy at the end of discharge event. Temperature de-rating in the second method uses lookup tables based on information provided by battery manufacturers or from discharge tests.

As noted, the first battery run time calculation method is more accurate at the beginning of a discharge cycle, but is less accurate at the end of the discharge cycle. Conversely, the second method is less accurate at the beginning of the discharge cycle, but is more accurate at the end of the discharge cycle. Therefore, it is beneficial to have a method whereby the two methods are blended to calculate the remaining battery run time. In one embodiment of the present invention, the run time computed in accordance with the first method is used for the first one-third of the discharge cycle. During the second one-third of the discharge cycle, the run times computed by the two respective methods are combined weighted linearly as a function of the state of charge. During the final one-third of the discharge cycle, the run time computed by the second method is used.

Determination of the state of discharge, i.e., which third of the discharge cycle the battery is in, is based on battery voltage and battery load in accordance with Fig. 18. As can be seen, there is a first third load vs. voltage curve and a second third load vs. voltage curve. For a given battery load, if the battery voltage is above curve, the battery module is deemed to be in the first third of the discharge and the discharge time calculated by the first method is used. If the battery voltage is between the curves then the module is deemed to be in the middle third of the discharge and the two run times computed by the two methods are linearly blended to produce a battery run time. Finally, if the voltage is below curve, then the battery is deemed to be in the final stage of the discharge and the run time computed in accordance with the second method is used. This weighting system is chosen based on empirical observation, and other weightings could be used without departing from the scope of the invention.

Flexible Module Location

Placing battery modules in any bay in the UPS frame allows the user to configure the UPS for maximum run time without using an external battery cabinet. Prior art modular UPS designs did not allow such flexible module placement. Flexible battery module location is accomplished in part by providing a battery module connector that is

- 23 -

identical to the power module connector. Additionally, the physical size of the battery modules and power modules is the same, allowing the two to be interchangeable. A third requirement for flexible battery module location is that the control signals not be location specific. In the UPS of the present invention, this is accomplished by controlling the modules using the control area network (CAN) bus to relay control signals. The CAN assigns an address to each module, and this address is independent of physical location. Although modules may generally be placed anywhere in the frame, power modules are restricted to certain slots as a function of the power capacity of the frame.

Safe Connector Housing

The hot swapable nature of the battery and power modules requires a safe connector that prevents a shock hazard to the user. To accomplish this, the modules are designed so that the printed circuit board card edge interfaces to standard wire terminated connector. Standard blind mate connectors available required metallic hardware, such as springs and screws, that increased the cost and complexity of the connector. The blind mate connector of the present invention is illustrated in Figs. 19 and 20. The blind mate connector of the present invention snaps into the UPS frame without hardware, but still allows floating connections for the printed circuit board. Floating connections are necessary to implement the flexible module location described above. The novel connector of the present invention also allows low power and high power connections in the same housing, which was not available with any of the available standard connectors. The connector of the present invention shrouds standard non-safe connectors, enabling them to meet agency safety requirements for hot-swapable modules.

The novel connector will now be described with reference to the exploded diagram in Fig. 19. The assembled connector is illustrated in Fig. 20. The novel connector principally comprises connector housing. In one embodiment, connector housing is constructed from molded plastic, although other materials or construction methods could be used. Connector housing is constructed so that it will snap into the sheet metal of the UPS frame. Connector housing is retained in UPS sheet metal by locking tabs. When connector housing is inserted into the sheet metal of the UPS frame, locking tabs snap in place preventing housing from being withdrawn from the sheet metal. Locking tabs prevent the connector housing from sliding all the way forward

- 24 -

through sheet metal. A symmetric set of locking tabs (not shown) is disposed on the underside of connector housing.

Connector housing also includes guide tabs disposed on the underside of connector housing. These guide tabs align with guide slots in the UPS frame sheet metal to roughly position connector housing. Guide tabs are slightly narrower than guide slots, and connector housing is slightly narrower than the opening in UPS sheet metal. This allows connector housing to float within opening for alignment when a UPS module is inserted for connection.

Connector housing is designed for use with standard power connectors and standard ribbon connectors. Power connector inserts into the rear of connector housing and is held in place by locking tabs. Similarly, ribbon cable connector inserts into the back of connector housing and is held in place by locking tabs. When power connector is inserted into connector housing, power connector terminals are aligned with opening in connector housing. When a module is inserted into the UPS frame, PCB card edge fingers will slide through opening and into power connector terminals, facilitating connection to UPS wiring connected to the back side of connector. Similarly, ribbon cable connector is used to connect various control signals. When control connector is inserted into connector housing, control connector terminals are aligned with opening in connector housing. When a module is inserted into the UPS frame, PCB card edge fingers will slide through opening and into power connector terminals, facilitating connection to a ribbon cable connected to the back of connector.

Seamless Transfer to/from Bypass

Another novel feature of the UPS of the present invention is the ability to seamlessly transfer from normal operation to bypass operation. Because the bypass system is housed in the UPS frame and is not modularly replaceable, it is desirable to provide higher reliability than may typically be had using semiconductor components. A contactor provides a non-semiconductor bypass element in the UPS frame. However, using non-semiconductor components generally results in a longer transition time than may typically be had using semiconductor components. To reliably use electro-mechanical components for bypass operation, it is necessary to minimize the dead time in the output voltage waveform due to the contactor's changing states. Minimizing the dead time has two components: (1) minimizing the time required for the bypass contactor

- 25 -

to change states and (2) centering this dead time about the zero crossing of the AC voltage waveform.

Overdriving the coil minimizes variations in the dead time from one contactor to another. On removal of the driving voltage the contactor reaches a high flyback voltage, which helps to minimize the dead time. By centering the contactor transition on the voltage zero crossing, the voltage dead time at a point where the instantaneous energy being delivered to the load is very small or zero.

Shipping Pallet

Another novel aspect of the UPS of the present invention is the pallet on which it is shipped. Construction and use of the pallet will now be described with reference to Fig. 6. Additional views and construction details may be seen in Figs. 7 through 10. Pallet is of wood construction, although other materials could also be used. A metallic bracing member provides additional support. The UPS is shipped with a protective material covering the UPS. To unload the UPS the protective material is removed. Brackets are connected to UPS and to the pallet to prevent the UPS from shifting in shipment. Brackets are secured to the pallet using bolts. Bolts are connected through holes in pallet. Brackets are affixed to the UPS by tabs, which fit into slots on the UPS.

During shipment, bracing member is affixed to pallet to provide additional structural rigidity to the shipping pallet. Bracing member may be constructed from any structurally sufficient metal, e.g., 14-gauge galvanized steel. Bracing member includes hole disposed so as to align with holes in the pallet. Thus, when the unit is assembled for shipping, bolts, which attach bracket to pallet also secure bracing member to the underside of pallet. To enhance the rigidity of bracing member, the sides of bracing member are formed into lips. Additionally, an end of bracing member forms lip.

Bracing member also serves as an unloading ramp when the UPS is to be removed from pallet. After brackets and bracing member have been removed, bracing member is inverted and lip is inserted into a slot in pallet, thus forming a ramp by which UPS may be removed from pallet.

An additional novel feature of this pallet is that it is forklift accessible on all sides. This is due to the construction using commercially available ORANGE SKID MATES (TM), which include padded feet. Because the pallet base is constructed using the ORANGE SKID MATES rather than traditional lumber framing of the prior art, the

- 26 -

pallet may be approached and lifted from all sides by a forklift. The shipping materials are also designed to be reusable to allow multiple shipments of UPS.

Various aspects and features of a novel uninterruptible power supply have been described herein. It will be appreciated by one of ordinary skill in the art that various modifications and adaptations of these features may be made without departing from the scope and spirit of the present invention. It is therefore intended that the scope of the invention not be limited to the disclosed embodiments, but rather be limited only by the scope of the following claims.

- 27 -

CLAIMS:

1. A method of equalizing output current among a plurality of alternating current devices connected in parallel, the method comprising:

5 measuring an output current of each device, thereby generating a plurality of output current signals;

selecting an output current signal having the largest magnitude, designated the highest output current signal;

providing the highest output current signal to a control input of each device;

10 comparing the output current signal for each device to the highest output current signal;

adjusting the output current of each device to match the output current corresponding to the highest output current signal.

2. A circuit for equalizing output current among a plurality of alternating current devices connected in parallel, the circuit comprising:

a plurality of current sensors, each having an output signal corresponding to an output current of a corresponding alternating current device;

a selection circuit having inputs receiving output signals from each current sensor and having an output signal corresponding to the current sensor output signal having the greatest magnitude;

20 a plurality of summing circuits, each having a first input receiving a corresponding current sensor output signal and having a second input receiving the selection circuit output signal, each summing circuit generating an output error signal corresponding to the difference between the selection circuit output signal and the corresponding current sensor output signal;

25 a plurality of control circuits, each receiving as an input the corresponding error signal and adjusting the output current of the corresponding alternating current device to minimize the magnitude of the error signal.

3. A power module comprising:
 - a PWM-controlled inverter
 - a current sensor, having an output signal corresponding to an output current of the power module;
 - a selection circuit having a first input receiving the output signal from the current sensor and having a second input receiving a signal corresponding to a highest output current of one or more other power modules connected in parallel with the power module, said selection circuit generating an output signal corresponding to larger of the current sensor output signal and the highest output current signal from the other power modules;
 - a summing circuit, having a first input receiving the current sensor output signal and a second input receiving the selection circuit output signal, the summing circuit generating an output error signal corresponding to the difference between the selection circuit output signal and the current sensor output signal;
 - a PWM inverter control circuit, receiving as an input the error signal and adjusting a PWM signal supplied to the inverter so as to cause the output current of the power module to minimize the magnitude of the error signal.
4. An uninterruptible power supply comprising one or more power modules in accordance with claim 3 connected in parallel.
5. A method of equalizing output current among a plurality of alternating current devices connected in parallel, the method comprising:
 - measuring an output power level of each device;
 - adding the output power levels for each device to arrive at a total output power;
 - dividing the total output power by the number of devices to derive an output power setpoint;
 - adjusting the output power of each device to match the output power setpoint.
6. An intelligent battery module comprising at least one battery string, a fuse, and a relay, all connected in series, the battery module further comprising a microprocessor based controller for monitoring and controlling the battery module components.

- 29 -

7. The intelligent battery module of claim 6 wherein the microprocessor monitors the charge status of the battery strings.
8. The intelligent battery module of claim 6 wherein the microprocessor controls the relay to disconnect the battery strings from a UPS bus when a failure of the battery strings is detected.
5
9. A UPS comprising one or more battery modules in accordance with claim 6, wherein the battery modules may be accommodated in any bay of the UPS frame.
10. The UPS of claim 9 further comprising one or more power modules in accordance with claim 3.
10
11. A method of battery module status monitoring comprising:
 - setting an empirical energy rating to an initial value corresponding to a manufacturer's rating of the battery module;
 - setting a present energy value equal to 0.9 times the initial empirical energy rating;
 - 15 determining the deliverable energy of the battery by multiplying the initial present energy by a temperature derating factor and a load derating factor;
 - updating the present energy value to account for charging or discharging of the battery;
 - updating the deliverable energy to account for temperature or load changes;
 - 20 updating the empirical energy rating at the end of a substantially full discharge cycle to equal the sum of the total energy delivered by the battery during the discharge cycle and the present energy value at the end of the discharge cycle.
12. A method of determining the battery run time of a UPS comprising a plurality of battery modules comprising the steps of:
 - determining the present energy stored in each battery module;
 - determining the deliverable energy stored in each battery module by multiplying the present energy of each battery module by a temperature derating factor and a load derating factor;
 - 25 determining the run time of the UPS by adding the deliverable energy of each battery module and dividing by the total load on the UPS.

- 30 -

13. A method of determining the state of charge of a plurality of battery modules in a UPS comprising the steps of:

determining an empirical energy rating for each battery module;
determining the present energy stored in each battery module;
determining the state of charge of the battery modules by adding the present energy of each battery module and dividing by the sum of the empirical energy rating for each battery module.

14. A floating safe connector consisting essentially of:

a connector housing receiving a standard connector; and
a plurality of locking tabs on the connector housing to retain the housing in the plane of an opening in a frame;

wherein the opening in the frame is sufficiently larger than the connector housing to allow the connector housing to move within the plane of the opening, and wherein the connector housing shrouds the energized parts of the standard connector.

15. A method of minimizing an interruption of an output voltage of a UPS during a bypass transition, the method comprising:

minimizing the time required for a bypass contactor to change states;
centering the time required for the contactor to change states about a zero crossing of the output waveform.

16. The method of claim 15 wherein minimizing the time required for the bypass contactor to change states is accomplished by overdriving a coil of the bypass contactor.

17. A shipping pallet comprising:

a pallet frame;
a plurality of padded feet affixed to a bottom of the frame;
a metallic bracing member affixed to the frame.

18. The shipping pallet of claim 17 wherein the metallic bracing member may be configured as a ramp for unloading the pallet.

19. A method of adjusting the state of charge of a battery module in a UPS, the method comprising:

periodically receiving time and date stamps from a control module;

- 31 -

storing the time and date stamps in a battery module controller memory when the battery module is removed from the UPS;

computing a time the battery module has been removed from the UPS when the battery module is re-inserted; and

5 adjusting the battery's capacity information to account for charge capacity lost during the time the battery module was removed from the UPS.

20. A method of adjusting the state of charge of a battery module in a UPS, the method comprising:

periodically receiving time and date stamps from a control module;

10 storing the time and date stamps in a battery module controller memory when the UPS is turned off;

computing a time the UPS has been turned off when the UPS is turned back on;

and

adjusting the battery's capacity information to account for charge capacity lost

15 during the time the battery module was removed from the UPS.

(71) Applicant: LIEBERT CORPORATION [US/US]; 1050 Dearborn Drive, Columbus, OH 43299 (US).

(72) Inventors: BLAIR, Charles, F.; 336 Grenn Meadows Dr. West, Powell, OH 43065 (US). GABEL, Mark; 2094 Stowbridge Rd., Dublin, OH 43016 (US). CRAWFORD, Chris; 9421 Din Eidyn Drive, Dublin, OH 43017 (US). WEBER, Dennis; 314 Bristol Woods Ct., Worthington, OH 43085 (US). BIRCHMEIER, John, R; 8379 Brible-tree Way, Columbus, OH 43235 (US). REINBOLT, Brad; 315 West 8th St., Hilliard, OH 43201 (US).

(74) Agent: BILLY, C., Allen, III; Howrey Simon Arnold & White, LLP, 750 Bering Drive, Houston, TX 77057-2198 (US).

(81) Designated States (national): AE, AG, AL, AM, AT, AU, AZ, BA, BB, BG, BR, BY, BZ, CA, CH, CN, CR, CU, CZ, DE, DK, DM, DZ, EE, ES, FI, GB, GD, GE, GH, GM, HR, HU, ID, IL, IN, IS, JP, KE, KG, KP, KR, KZ, LC, LK, LR, LS, LT, LU, LV, MA, MD, MG, MK, MN, MW, MX, MZ, NO, NZ, PL, PT, RO, RU, SD, SE, SG, SI, SK, SL, TJ, TM, TR, TT, TZ, UA, UG, UZ, VN, YU, ZA, ZW.

(84) Designated States (regional): ARIVO patent (GH, GM, KE, LS, MW, MZ, SD, SL, SZ, TZ, UG, ZW). Eurasian patent (AM, AZ, BY, KG, KZ, MD, RU, TJ, TM). European patent (AT, BE, CH, CY, DE, DK, ES, FI, FR, GB, GR, IE, IT, LU, MC, NL, PT, SE, TR). OAPI patent (BF, BJ, CF, CG, CI, CM, GA, GN, GW, ML, MR, NE, SN, TD, TG).

Published:
— with international search report

(88) Date of publication of the international search report: 25 April 2002

For two-letter codes and other abbreviations, refer to the "Guidance Notes on Codes and Abbreviations" appearing at the beginning of each regular issue of the PCT Gazette.

(54) Title: MODULAR UNINTERRUPTIBLE POWER SUPPLY

(57) Abstract: A modular uninterruptible power supply is disclosed, which provides complete redundancy for all components required for UPS operation. Novel aspects of the invention include design of the modules and their interconnection and interoperability, as well as improved operation techniques applicable to UPS systems generally.

INTERNATIONAL SEARCH REPORT

International Application No
PCT/US 01/05254

A. CLASSIFICATION OF SUBJECT MATTER
IPC 7 H02J9/00 H02J9/06 H02J3/00

According to International Patent Classification (IPC) or to both national classification and IPC

B. FIELDS SEARCHED

Minimum documentation searched (classification system followed by classification symbols)
IPC 7 H02J H02M

Documentation searched other than minimum documentation to the extent that such documents are included in the fields searched

Electronic data base consulted during the international search (name of data base and, where practical, search terms used)
EPO-Internal, WPI Data

C. DOCUMENTS CONSIDERED TO BE RELEVANT

Category *	Citation of document, with indication, where appropriate, of the relevant passages	Relevant to claim No.
X	PINA MARTINS A ET AL: "A CONTROL METHOD FOR HIGH POWER UPSS IN PARALLEL OPERATION" 38TH. MIDWEST SYMPOSIUM ON CIRCUITS AND SYSTEMS: PROCEEDINGS. RIO DE JANEIRO, AUG. 13 - 16, 1995, MIDWEST SYMPOSIUM ON CIRCUITS AND SYSTEMS: PROCEEDINGS, NEW YORK, IEEE, US, vol. 1 SYMP. 38, 13 August 1995 (1995-08-13), pages 208-211, XP000684550 ISBN: 0-7803-2973-2 page 209, left-hand column, paragraph 5	5
X	DE 36 02 496 A (KLEIN KG ELEKTRO GERAETE G) 30 July 1987 (1987-07-30) column 6, last paragraph -column 7, paragraph 2; figure 1	5

Further documents are listed in the continuation of box C.

Patent family members are listed in annex.

* Special categories of cited documents :

- "A" document defining the general state of the art which is not considered to be of particular relevance
- "E" earlier document but published on or after the international filing date
- "L" document which may throw doubts on priority claim(s) or which is cited to establish the publication date of another citation or other special reason (as specified)
- "O" document referring to an oral disclosure, use, exhibition or other means
- "P" document published prior to the international filing date but later than the priority date claimed

"T" later document published after the international filing date or priority date and not in conflict with the application but cited to understand the principle or theory underlying the invention

"X" document of particular relevance; the claimed invention cannot be considered novel or cannot be considered to involve an inventive step when the document is taken alone

"Y" document of particular relevance; the claimed invention cannot be considered to involve an inventive step when the document is combined with one or more other such documents, such combination being obvious to a person skilled in the art.

"&" document member of the same patent family

INTERNATIONAL SEARCH REPORT

International application No.
PCT/US 01/05254

Box I Observations where certain claims were found unsearchable (Continuation of item 1 of first sheet)

This International Search Report has not been established in respect of certain claims under Article 17(2)(a) for the following reasons:

1. Claims Nos.: because they relate to subject matter not required to be searched by this Authority, namely:

2. Claims Nos.: because they relate to parts of the International Application that do not comply with the prescribed requirements to such an extent that no meaningful International Search can be carried out, specifically:

3. Claims Nos.: because they are dependent claims and are not drafted in accordance with the second and third sentences of Rule 6.4(a).

Box II Observations where unity of invention is lacking (Continuation of item 2 of first sheet)

This International Searching Authority found multiple inventions in this international application, as follows:

see additional sheet

1. As all required additional search fees were timely paid by the applicant, this International Search Report covers all searchable claims.

2. As all searchable claims could be searched without effort justifying an additional fee, this Authority did not invite payment of any additional fee.

3. As only some of the required additional search fees were timely paid by the applicant, this International Search Report covers only those claims for which fees were paid, specifically claims Nos.:

4. No required additional search fees were timely paid by the applicant. Consequently, this International Search Report is restricted to the invention first mentioned in the claims; it is covered by claims Nos.:

1-5

Remark on Protest

The additional search fees were accompanied by the applicant's protest.
 No protest accompanied the payment of additional search fees.

FURTHER INFORMATION CONTINUED FROM PCT/ISA/ 210

This International Searching Authority found multiple (groups of) inventions in this international application, as follows:

1. Claims: 1-5

Equalization of output power of parallel connected supplies

2. Claims: 6-13,19,20

Intelligent battery monitoring and control

3. Claim : 14

Connector

4. Claims: 15,16

Bypass contactor control

5. Claims: 17,18

Shipping pallet
